INTRODUCTION

In July 1970, Moss Landing Marine Laboratories began a limited qualitative survey of the benthic infauna at several shallow water stations in northern Monterey Bay to gather baseline information on the species composition of the benthic communities. Based on the experience and the data obtained during this investigation, a more extensive study was initiated in August 1971. The two principal objectives of this study were to obtain quantitative information on the composition of the shallow water benthic infauna communities of northern Monterey Bay and to evaluate their natural variation in time and space. Permanent stations were chosen which represented the major depth and sediment regimes of the shallower water of northern Monterey Bay. In addition, several stations were placed in areas which are likely to be affected by waste disposal in the near future. Wherever possible, the location of stations was chosen to coincide with sampling stations used by other participants in the Sea Grant program for gathering data on hydrography, phytoplankton biomass, and productivity. This insured that a maximum amount of information would be available for analyzing the temporal and spatial differences of the benthic infaunal communities. The sampling procedures we used were similar to those employed by Dr. Welton Lee of Hopkins Marine Station and Dr. Eugene Haderlie of the United States Naval Postgraduate School in their survey of the benthic infauna of southern Monterey Bay. The similar techniques should permit the comparison of data from the two halves of the bay.

This final data report discusses the methods we employed in the survey and gives the initial reduction of the data on the benthic infauna for the period of August 1971 through February 1973. This report does not represent final data analysis, nor does it discuss community structure and temporal variation. It is merely a data report.

We have collected 383 species of infaunal organisms and have identified and enumerated 137,465 individuals. Due to the magnitude of the taxonomic difficulties involved, our time has been almost entirely occupied by this task. Detailed analyses and interpretations of the data presented here are currently being initiated by the scientific personnel involved in the project and upon completion will be submitted for publication to appropriate scientific journals.

Initially the study was supported solely by a grant from the Office of Sea Grant Programs, U.S. Department of Commerce. From September 1971 through August 1972, substantial additional support was received from the Association of Monterey Bay Area Governments (AMBAG). This support enabled us to expand and improve the project.

SCIENTIFIC PERSONNEL

<u>Individual</u>	<u>Specialty</u>
James Nybakken Associate Professor	Project Director
Alfred Hodgson Chief Systematist	Polychaeta and Ophiuroidea
Patrick Clark Research Assistant	Bivalvia
Gary McDonald Research Assistant	Opisthobranchia

Michael Panietz Research Assistant	Polychaeta
David Shonman Research Assistant	Gastropoda and Scaphopoda
Peter Slattery Research Assistant	Crustacea and Ophiuroidea
Barry Turner Research Assistant	Polychaeta

In addition to the above personnel, students employed as hourly help and students enrolled in the undergraduate research class "Environmental Research Participation" have greatly aided in shipboard sampling and laboratory sorting of samples.

ACKNOWLEDGEMENTS

We are most grateful to the following taxonomic experts for their courtesy in identifying and/or confirming determinations of specimens of organisms collected during this study. Without their help, a project such as this would not have been possible. However, the acknowledgement of their invaluable assistance does not imply that they have checked all of the species listed in this report or all of the individuals of a given species.

We are also greatly indebted to Frank Monnich, owner and Captain of the research vessels AMIGO and FALCON, for providing us with the ship time necessary for the collection of our samples.

METHODS AND MATERIALS

Choice of Stations

Sampling began at ten permanent stations in August 1971. The locations of these stations were chosen to cover a large area of the bay north of the Monterey Submarine Canyon and to represent a wide range of depth and sediment types. Areas with rocky substrata were avoided. The steep slopes of the canyon wall were also avoided due to the difficulty of maintaining the ship over a constant depth while sampling.

These ten permanent stations were also used for the AMBAG project. Two stations were added at the request of AMBAG. However, the one new station located outside the bay had to be eliminated, leaving eleven permanent stations. The locations and depths of these stations are listed in Table 1. Figure 1 shows their locations within the bay.

Navigation

Station positions were determined using a combination of loran, radar ranges and bearings, and fathometer readings. In most cases the accuracy of the position was about ± 0.1 nautical mile. The ship was not anchored at the stations so the amount of drift was constantly observed and recorded. If the depth changed more than a few meters, or if

NORTHERN MONTEREY BAY

Figure 1

the ship drifted more than 0.3 nautical mile during sampling, we returned to the correct position to take the remainder of the replicate samples.

Number of replicate samples

Samples were collected with the Smith - McIntyre grab (McIntyre 1954) which has a sampling area of 0.1 m^2 . Initially eight replicates for faunal analyses were taken at each station. This was the number of replicates used by Drs. Lee and Haderlie for their survey in southern Monterey Bay. The number of replicates was later decreased to six due to time and financial limitations. This number was felt to be sufficient based on data reported by Lie (1968) for a similar quantitative study of the benthic infauna in Puget Sound. He considered five 0.1 m^2 replicate samples to be adequate to statistically describe the faunal assemblages and to obtain data on the ecology and biology of the most important species. In the May 1972 sampling period, we initiated more intensive sampling at station 1105 (Figure 1). The number of replicates was increased from six to ten in order to improve our ability to detect short term temporal variations at that station.

To determine if the number of species at a station was being adequately sampled with six replicates, cumulative plots of the number of species added versus increased sampling area were constructed for three stations (Figure 2). The plots represent the average values for two random orders of the replicates. Figure 2 shows that 91% to 96% of the species found in eight replicates will be obtained in six replicates at these stations. At station 1105, 86% of the species in ten replicates will be obtained in six replicates. Due to the dominance of the infaunal

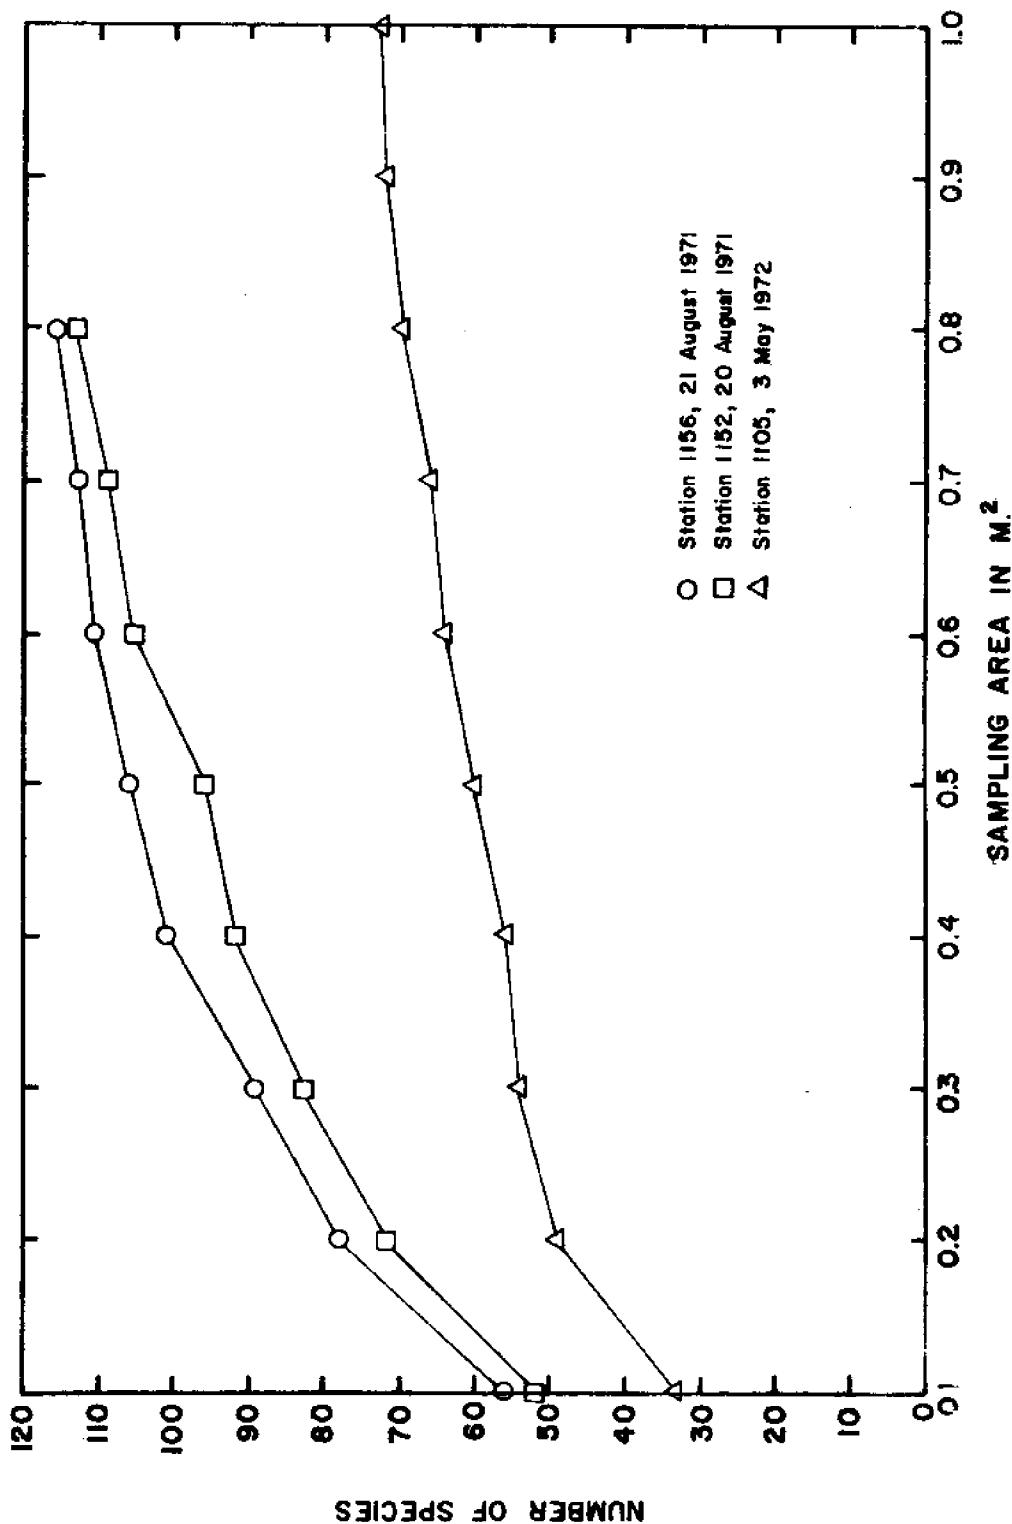

Figure 2. Cumulative plots of the number of species added versus increased sampling area, for three stations

communities by a small number of species (Tables 5 - 70), the species added in succeeding replicates are generally the rarer species. Therefore, six replicates are adequate for sampling the dominant species at a station. Table 2 shows the number of replicate samples at each station for each sampling period throughout the investigation.

Performance of the Smith-McIntyre grab

Variability in the volume of sediment obtained at each station was used to evaluate the ability of the Smith-McIntyre grab to take reliable replicate samples. Table 2 shows the mean volume of sediment obtained at all of the stations throughout the period of investigation. The coefficient of variation equals 100 (Standard deviation / mean volume). Good replication should produce a low coefficient of variation. The average coefficient of variation of mean sediment volumes from all stations decreases from 26% to 13% through the sampling periods (Figure 3). At the same time the average volume of mean sediment volumes from all stations increases from 4.5 to 9 liters (Figure 4). The correlation between these values is highly significant ($p < .001$, correlation coefficient), demonstrating that the average mean coefficient of variation for all stations decreases with increasing average mean volume of sediment throughout the period of investigation. This trend is attributable to the effect of experience of the crew in operating both the ship and the sampling gear. The effect of weather is probably minimal as wind and sea conditions were considerably variable and did not follow the trend of decreasing through the sampling periods.

The coefficient of variation is a measure of the variation in depth

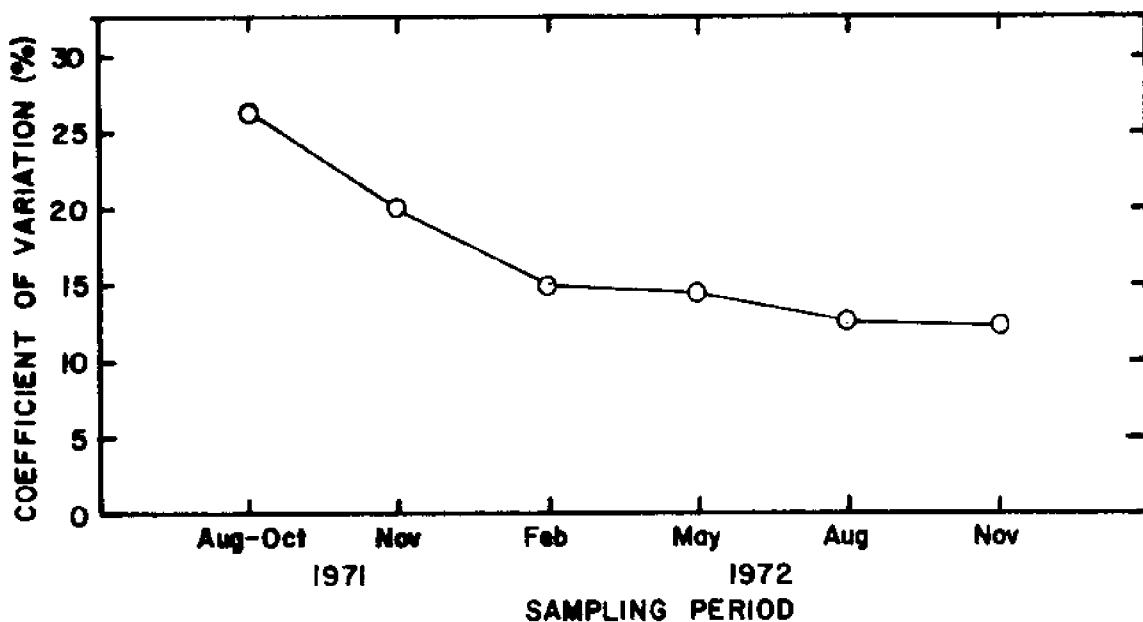

Figure 3. Average coefficient of variation of mean sediment volumes in replicate grab samples from all stations

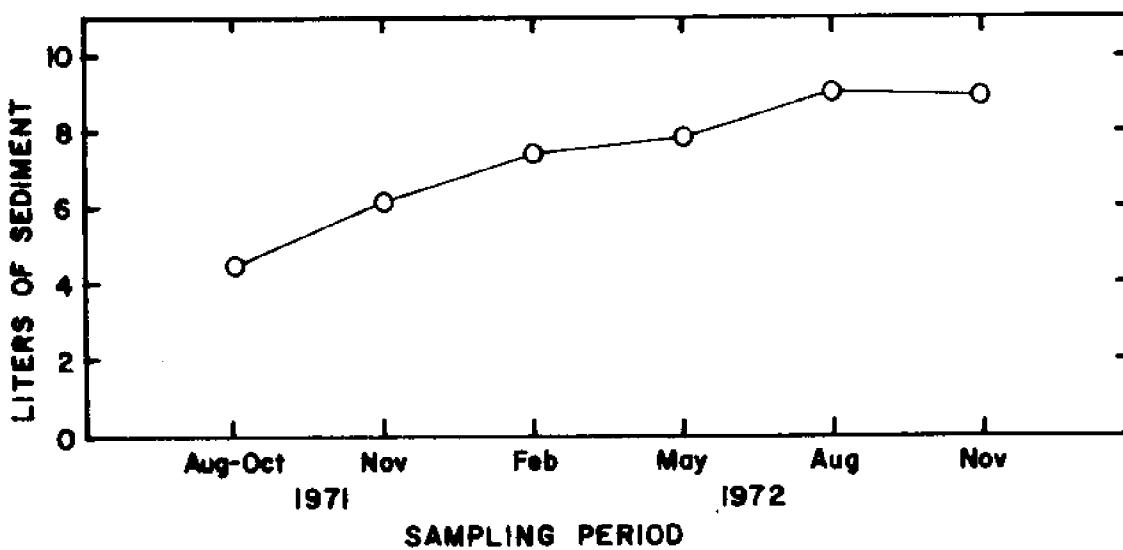

Figure 4. Average volume of mean sediment volumes in replicate grab samples from all stations

of penetration of the grab. An experienced crew can achieve a mean coefficient of variation for all stations of approximately 13% with a mean volume of sediment of 9 liters, indicating an average penetration of 10 cm. However, the volume of sediment obtained at stations with a high percentage of sand (Table 4) was considerably less. Analysis showed that the average volume of sediment in replicate grab samples was highly negatively correlated with percent sand composition of the sediments ($p < .001$, correlation coefficient). From February 1972 through November 1972, when the crew's sampling experience was high, some replicates with a minimum volume of 4 liters, representing 5 cm penetration, were taken at the sandy stations (Table 2). In an investigation conducted by John Oliver of Moss Landing Marine Laboratories on a sandy bottom in 20 meters of water near Moss Landing, twenty-four percent of the total number of infaunal organisms were found to inhabit depths greater than 5 cm. Nine percent were found at depths greater than 10 cm. If the vertical distribution of the infauna in mud is similar (Molander 1928) the effect of sampling variability on faunal parameters can be expected to be higher at sandy stations than at stations with softer sediments even though the coefficients of variation may be equal.

Sieve mesh size

All of the samples were sieved through a Nytex screen with a 1.0 mm mesh size which was backed up by another screen with a 0.5 mm mesh size. Initially only those organisms which were retained by the 1.0 mm mesh size screen were saved for faunal analyses. At station 1105, from May 1972 through February 1973, we also identified and enumerated those organisms

retained by the 0.5 mm mesh. Table 3 compares the 1.0 mm mesh screen to the combination of the two screens with respect to the total numbers of species and individuals obtained.

Table 3

Total number of species and individuals obtained at station 1105 with a 1.0 mm mesh screen and the 1.0 mm plus 0.5 mm mesh screens.

11 Nov 1972	64		2035	72	4051
28 Feb 1972	49		694	58	1454

Reish (1959) discusses the importance of screen size in washing quantitative benthic samples. We considered the 1.0 mm mesh size appropriate for this survey, due, primarily, to the prohibitive time factor involved in identifying and enumerating the organisms retained by a 0.5 mm mesh screen. However, some information about the seasonality of important infaunal species was lost, as many of the individuals retained by the 0.5 mm mesh screen were juveniles. In May and August, additions of primarily juvenile forms of four species accounted for 56% and 80%, respectively, of the increases shown in the total numbers of individuals (Table 3). The increases in the numbers of species were due, largely, to additions of rare species.

Sampling Procedures

In each of the six replicates, the depth of the sediment contained in the grab was measured through a door on the top of the bucket. This measurement was used to determine the volume of sediment. At the same time, we measured the temperature of the sediment and removed a small subsample with an 8 cm long plastic cover for sediment particle size analysis and organic carbon determination. The contents of the grab were then emptied into a styrofoam ice chest for storage until they could be sieved. From November 1971 through February 1972, an additional grab sample was taken at each station to obtain sediment for heavy metal determination and DDT and nutrient uptake analyses.

Sieving was done on board ship. The sample was washed from the ice chest onto the screen with a hose. Water used in this operation was pumped from the bay through a filter to remove all planktonic organisms larger than the mesh size used for sieving. A low water pressure was maintained to prevent unnecessary damage to the specimens.

Larger polychaetes were picked from the screen while the sample was being sieved. They were relaxed in propylene phenoxetol diluted 1:99 with sea water, bottled, and preserved in 10% formalin buffered to neutral pH with hexamethylenetetramine. Ophiuroids were also picked from the screen during the sieving process, killed by placing in distilled water, bottled separately, and preserved in 10% buffered formalin. All of the material left on the screen after sieving was placed in a jar containing sea water with magnesium chloride (73 grams / liter) and rose bengal. This relaxed and stained the organisms. The sample was allowed to stand for about an hour and then preserved with 10% buffered formalin.

Sampling Dates

Samples were collected at each station once every three months during the period of investigation. Table 2 lists the sampling dates. In February 1973 we took samples only at station 1105 which had been under the influence of a heavy discharge from the Pajaro River during the winter months.

Sorting and Identification of the Fauna

The preserved samples were brought back to the laboratory for sorting. Small portions from the jars containing the screen residue were placed in glass petri dishes with fresh water, and the organisms were picked out under a dissecting microscope with fine forceps. The rose bengal had stained the organisms pink so that they were more readily separated from the sediment and debris. The fauna was sorted into six major categories: Polychaeta, Bivalvia, other Mollusca, Crustacea, Echinodermata, and miscellaneous phyla. These were bottled separately and preserved in 70% ethanol. This initial rough sorting was done by several part time employees.

The bottles of Polychaeta, together with the jars of larger Polychaeta separated on board ship, were further sorted into families before identifications to the lowest possible taxa were made. The other major categories of organisms were sorted directly to the lowest taxa. We put most of our taxonomic efforts into the five major classes of infaunal organisms; Polychaeta, Gastropoda, Bivalvia, Crustacea and Ophiuroidea. The other classes of organisms received less attention.

We are currently in the process of establishing a reference collection of all of the species of organisms collected by this survey. This collection will be catalogued and maintained in the museum at Moss Landing Marine Laboratories. In addition to the reference collection, the laboratory will store, at least temporarily, all of the organisms that were obtained during this survey. The California Academy of Sciences has expressed an interest in receiving all of the organisms except the reference collection. We may transfer our material there.

Some of the identifications given to organisms in this report are still subject to revision pending further examination by experts. In addition, there are a number of species which do not appear to be described in the literature. It is hoped that eventually descriptions will be made from our material and published.

Sediment Particle Size Analysis

The 72 subsamples collected in November 1972 were analyzed for sediment particle size using standard procedures. (Carver 1971, Emery, 1938). The samples were initially treated with 35% hydrogen peroxide to remove the organics. The silt and clay fractions were then separated from the coarser fractions by dry sieving through a 4-phi screen. Silt was separated from clay by pipette analysis and the sand was further divided into coarse, medium, and fine portions by Emery tube analysis. There was no gravel fraction. The results are presented in Table 4 as mean percent weights for each size fraction. The number of subsamples used for calculating the means equals the number of replicates for a station.

EXPLANATION OF DATA TABLES AND FIGURES

Tables 5 - 70 list the major classes and species of organisms found at each station throughout the period of investigation. Only identified species of organisms having a mean number of individuals of 2.00 or greater per $0.1m^2$ are reported. The organisms falling into the category of miscellaneous phyla are excluded. The choice of a mean of 2.00 individuals / $0.1m^2$ as a cutoff point was arbitrary but is based on the fact that a taxon must be present in reasonable numbers before it can be treated quantitatively. The choice of a mean of 2.00 or greater per $0.1m^2$ leaves an average of 21 species that are reported at each station for each sampling period. These species account for 63% of the total number of individuals collected during the survey and, therefore, comprise the major components of the fauna. The number of replicates for a station is used for calculating the mean. The variance is symbolized by S^2 . The Conf. limits are the 95% confidence limits. Percent of the total means percent of the total number of individuals collected at that station for that sampling period. Percent of the total for species are listed under sp. Values for classes are listed under Cl. Classes and species are listed in the order in which they are reported in the species list (Table 71).

Station 1155 was not sampled in August - October 1971. Data for Bivalvia in November 1972 and February 1973 are also missing as identifications of these organisms have not been completed.

Table 71 lists all of the genera and species that were recorded during the investigation along with the author and date of the original

description. Organisms identified to specific level, but for which a specific name is not presently available, are designated by lower case letters (e.g. Phyllodoce sp. a). Organisms identified to generic level only are designated by sp. if singular or spp. if more than one individual is present. An exception is the Bivalvia in which no distinction is made between individuals identified to the specific level, for which no specific name is available, and those individuals only identified to the generic level.

Polychaeta are listed by families. The order of families is the phylogenetic order recognized by Hartman (1968, 1969). Species are listed alphabetically under each family. Gastropoda are listed alphabetically by subclass. Crustacea are ordered alphabetically by order with the exceptions of the Amphipoda, which are listed alphabetically by family, and the Decapoda, which are listed by suborder. The arrangement of subclasses and orders of Crustacea is the phylogenetic order recognized by Meglitsch (1967).

This table also shows the distributions of genera and species among the eleven stations from October 1971 through February 1973. A "+" denotes that the taxon was present at the station indicated at least once during the period of investigation but was never represented during any sampling period by a mean number of individuals equal to or greater than 2.00 per $0.1m^2$. A "C" (= common) indicates that a taxon was represented during at least one sampling period by a mean of 2.00 per $0.1m^2$ or greater but less than 20.00 individuals per $0.1m^2$. If the numbers of individuals of a taxon were present at a station at any time

in numbers exceeding 20.00 per $0.1m^2$, this is designated by "A" (= abundant).

Figures 7-41 show the numbers of species of organisms and numbers of individuals per $0.1m^2$ and the 95% confidence limits from each sampling period for total fauna, Polychaeta, Gastropoda, Bivalvia, Crustacea, and Ophiuroidea. The number of species is the total number found in the combined replicates for a station. The mean number of individuals and confidence limits are calculated from the total number of replicates for a station (Table 2).

The order of the stations is constant for Figures 7-41. This order is derived from the depths and sediment parameters of the stations. The stations can be separated into four depth categories (Table 1); 14.5 m to 16.5 m, 25.5 m, 34.5 m to 37.0 m, and 62.5 m to 63.0 m. Table 4 gives the mean percent weight of sediment fractions at the eleven stations in November 1972. Figure 5 shows the percent weights of the sand fractions and the 95% confidence limits in order of decreasing values. Figure 6 shows the percent weights of the clay fractions, and the 95% confidence limits in order of increasing values. The ordering of the stations in the two figures is the same except for station 1153.

Sanders (1956, 1958) found that clay content is the most valid sediment particle size parameter for determining faunal distributions. Indirectly, depth may also be related to the distributions of the infauna as Nichols (1970) has shown. Based on this information, the eleven stations have been ordered within their depth categories by increasing percent clay composition in an attempt to approximate a natural order.

Table 4

Mean percent weight of sediment fractions
at the eleven benthos stations in November 1972.

<u>Station</u>	<u>Coarse sand</u>	<u>Medium sand</u>	<u>Fine sand</u>	<u>Sand</u>	<u>Silt</u>	<u>Clay</u>	<u>Silt and clay</u>	<u>Sand / mud</u>

Table 70

**Major classes and species of organisms at
Station 1105, 28 Feb 1973**

Summary: Bivalvia not included

Number of replicates: 10

Total number of identified species: 49

Total number of individuals: 694

<u>Class</u>	<u>Number of species</u>	<u>Percent of total identified species</u>
Polychaeta	27	55
Gastropoda	4	8
Bivalvia		
Crustacea	16	33
Ophiuroidea	1	2
Total	48	98

Numbers of individuals in major classes and species:

<u>Taxa</u>	<u>Mean # / .1m²</u>	<u>S²</u>	<u>Conf. limits</u>	<u>Total #</u>	<u>% of total sp. Cl.</u>
POLYCHAETA	26.30	32.68	4.09	263	37.9
<u>Nothria elegans</u>	7.90	7.21	1.92	79	11.4
<u>Lumbrineris luti</u>	2.30	3.12	1.26	23	3.3
<u>Magelona sacculata</u>	2.50	3.17	1.27	25	3.6
<u>Chaetozone setosa</u>	2.90	8.10	2.03	29	4.2
GASTROPODA	8.70	12.90	2.57	87	12.5
CRUSTACEA	31.70	102.68	7.24	317	45.7
